The last issue of the Food Talk insert included information about food allergies: how major food allergens are listed, what the eight major food allergens are, and symptoms of allergic reactions.

With food allergies still on the rise and no clear answer to their cause, allergic people anxiously await the development of an effective treatment to prevent life-threatening reactions. Researchers are making progress with a method for helping children with food allergies develop a tolerance for foods they otherwise couldn't eat. The technique is called immunotherapy. The basic idea is to give an allergic child extremely small quantities of the allergen and increase the dosage over time. A recent study in the New England Journal of Medicine, is particularly exciting because it followed children with an egg allergy for one year after they stopped receiving immunotherapy treatment and found some success with that group. Following 22 months of treatment, 75% of kids who received immunotherapy were considered "desensitized" to eggs. It's important to note, however, that 15% of kids receiving the immunotherapy treatment dropped out of the trial-mostly because of allergic reactions. Before this method could become the standard of care, doctors must further investigate what are the risks of undergoing treatment compared with just trying

to live with the allergy and avoiding the offending food. Authors also can't rule out the possibility that some children were in the process of naturally outgrowing their egg allergies.

This study is a major investment in moving towards a treatment; however, it could be 5-10 years before it is determined if the outcome is truly a long-term immune tolerance of allergens.

In the meantime, don't try this at home. This procedure was done in a medical setting under tightly controlled conditions.
